INTRODUCTION

Quaternary geology mapping, test drilling, monitor well installation and water level measurements have been conducted, in the settled area of Saskatchewan by a number of agencies including: Saskatchewan Research Council (SRC), Sask Water Corporation (SWC), Prairie Farm Rehabilitation Administration (PFRA) and others, during the past 50 years. Data collected during these investigations provides a basis for the evaluation of palatable groundwater resources in Saskatchewan. The objective of this investigation is to continuously improve the understanding of provincial groundwater resources, in terms of occurrence, quantity, quality, and behaviour, in order to support the development, management, and protection of these water supplies.

With this need in mind, the Saskatchewan Research Council (SRC) has worked co-operatively with SaskWater to complete a new Geology and Hydrostratigraphic/Groundwater Resource map series corresponding to the 1:250,000 scale, National Topographic Series (NTS) areas of Saskatchewan. This work is an update and refinement of maps published by SRC during the late 1960's and 1970's.

The present report accompanies the preliminary maps and cross sections depicting the geology and hydrostratigraphy in the Wynyard Area (72P). The updated maps post empirical aquifer information for wells completed at specific locations throughout the area.

METHODOLOGY

Stratigraphic cross sections were prepared along 12 profiles which display the stratigraphic continuity between testholes and wells in the Wynyard Area. These cross sections were constructed utilizing lithologic testhole data obtained from the Sask Water data base, and additional testhole records stored at SRC. A database of a hydrostratigraphic and/or lithostratigraphic picks for each well used in the study was prepared. These picks consisted of recognized lithological units and/or stratigraphic picks based on testhole cutting descriptions, electric logs (eg. sand units, bedrock formations, group breaks, surficial sand etc.) and picks made from previous studies (e.g. Henry et al., 1990, Mclean, 1971, Maathuis & Schreiner, 1982).

Map coordinates (UTM- NAD83) were generated for each well/testhole by determining the location of the centroid of the most accurate, dominion land location description reported (i.e. well locations reported to a legal sub-division (lsd) location were assigned the UTM point coordinate located at the centre of that lsd etc.). Cross section were created by selecting wells from a map display of well locations, using an AutoCAD autolisp routine called "AutoWell". This program hung lithologic strip logs at the location and elevation of each well along the cross section. Stratigraphic correlations and picks were then refined and edited by interpreting and extrapolating stratigraphic data from one well to the next. These roughly parallel cross sections were spaced approximately 14 to 19 km apart: 6 in a north-south orientation, and 6 traversing the study area in an east-west direction.

The testholes used in this study included those testholes with electrical logs (oil and potash exploration testholes), testholes and observation wells drilled by SRC (comprised of electrical logs, driller's logs, and geologist's descriptions), and farm or municipal water-well testholes (comprised of electrical logs and driller's logs), which were drilled with the assistance of Sask Water. In all 1,078 individual testhole/waterwell records were utilized in the compilation of the is report. Map 1 shows the location of the 12 cross sections and testhole/waterwell locations in the Wynyard Area.

A map showing the bedrock surface geology and topography was prepared (Map 2). Maps indicating the geographic extent of the aquifers were completed for each stratigraphic level at which aquifers or potential aquifers (i.e. sands and gravels) occur (Maps 3-7). In some cases, aquifers from different stratigraphic positions may be shown on one sheet. The aquifer maps include specific information pertaining to wells/testholes including depth to, thickness of the deposit, and the static water level when reported. Initial preparation of these maps was completed with the use of the Geographic Information System (GIS) software ArcView (ver 3.1). The GIS enabled the spatial display and query of the database of stratigraphic and aquifer information, which had been prepared from the water well and testhole information.

Upon completion of the aquifer map compilations, the line work was digitized and saved as *.dwg, AutoCad 14 drawing files. These layers were then combined with a digital base map of the Wynyard Area (1:250,000 scale) licenced by SaskWater from SaskGeomatics, for this report . Hard

copy aquifer maps were plotted at a scale of 1:200,000. The accompanying cross sections are plotted at the same horizontal scale of 1:200,000 with a vertical exaggeration of 50x.

GEOLOGY

General

Topographic surface elevations in the Wynyard Area range from 500 metres above sea level (masl) in the vicinity of Last Mountain Lake to elevations in excess of 730 masl in Touchwood Uplands located in the southeast portion of the area. All sediments between the bedrock surface and the present surface are considered to be “drift”.

The bedrock surface topography in the Wynyard area was modified by several significant events: preglacial erosion, glacial and fluvio-glacial erosion, and subsurface collapse. In preglacial time, fluvial drainage systems flowed from the Rocky Mountains region eastward across Saskatchewan, and were responsible for the deposition of significant accumulations of sediments within valleys eroded into the bedrock surface (eg. Hatfield Valley). Later, erosion by continental glaciers and subsequent meltwater modified the surface topography in the Wynyard area significantly. The bedrock surface was further modified by subsurface collapse events as a result of the removal of salt by groundwater from the stratigraphically lower, Prairie Evaporite Formation (McLean, 1971). Evidence of salt collapse is indicated along many of the cross sections in the Wynyard map area, particularly sections C-C' and D-D, where it is obvious that faulting and subsequent displacement of the Judith River and Bearpaw Formations is a result of subsidence related to the removal of the underlying salt beds.

The drift in the Wynyard Area ranges in thickness from a maximum of 200 metres in the southwestern portion of the Wynyard Area, to a minimum of a few metres in the Quill Lakes area where Tertiary aged bedrock is covered with thin layer of drift. At other locations isolated outcrops of bedrock (Cretaceous Bearpaw Formation) are exposed along glacial meltwater spillway channels which have eroded through the drift sequence (i.e. Last Mountain Lake Spillway).

Glacial ice eroded, but also deposited material, mainly till, an unsorted mixture of sand, silt, clay, pebbles, and boulders. As the ice retreated from the area, large volumes of meltwater were released. Flowing meltwater eroded existing materials and deposited stratified gravels, sands along meltwater channels and spillways. Accumulations of meltwater formed glacial lakes which resulted in the deposition of glaciolacustrine sand, silt, and clay. This process of erosion and deposition of till and

stratified deposits occurred several times as the ice repeatedly advanced and retreated over the area. This sequence of events resulted in the drift stratigraphy that presently exists.

The drift has been divided into three groups; Empress Group, Sutherland Group, and Saskatoon Group. The Empress Group consists of stratified gravels, sands, silts, and clays that occur between the bedrock surface and the first or lowest till (Whitaker, Christiansen, 1972). Where information makes it possible the Sutherland Group may be divided into the: Warman, Dundurn, and Mennon formations; and the Saskatoon Group into Floral and Battleford formations (see Table 1). The definition of these groups and the description of the typical drift units forming the stratigraphy are provided by Christiansen (1968, 1992) and Whitaker and Christiansen (1972). The subdivision of the drift into its various formations is presently not possible throughout all of the Wynyard Area, due to the lack of quality data and testhole logs.

| Period | Stratigraphy | | Lithology | Hydrostratigraphic Units Rosetown Area | | |

Modified after Christiansen, 1992

Table 1. Schematic hydrostratigraphic setting of the study area.

Bedrock

Lea Park Formation and Upper Colorado Group

The Lea Park Formation cannot be differentiated from Upper Colorado Group on the basis of electric logs which are the dominant type of information available from the testhole which penetrate to this depth (Christiansen,1979). In this study, these two units will be referred to as one. The unit is composed of noncalcareous, gray, marine silt and clay, and is found throughout the entire Wynyard map area. The bottom of the Upper Colorado Group is marked by the base of the Second White Speckled Shale. This unit serves as a marker bed to separate the Upper and Lower Colorado Group sediments. The Lower Colorado Group sediments are composed of calcareous, gray, marine silt and clay, and is found throughout the entire Wynyard map area.

Judith River Formation

The Judith River Formation is an eastward thinning sedimentary wedge, composed predominantly of clays, silts and sands deposited in a non-marine environment. The Judith River is overlain by the Bearpaw Formation and underlain by the Lea Park, both westward thinning wedges composed predominantly of clays and silts deposited in a marine environment. (McLean, 1971).

The Judith River formation is only present in the western portion of the study area. Eastward, the formation either pinches out, or was eroded during the deposition of the Hatfield Valley, a preglacial channel which had eroded down through the entire thickness of the Bearpaw Formation and Judith River Formation. The position of the Judith River Formation is not precisely known due to the fact that insufficient data are available (Maathuis and Schreiner, 1982). Thickness of the formation ranges from 0 m (absent) to 60 m in the southwest part of the Wynyard area (Section F-F').

Bearpaw Formation

The Bearpaw Formation overlies the Judith River Formation in the western portion of the Wynyard area. In the Wynyard area the Bearpaw Formation is composed of soft, gray, noncalcareous, marine, silt, and clay. Minor sand layers are present in the extreme southwest portion of the study area (Ardkeneth Member).

Pierre Shale

The Pierre Sale is the stratigraphic equivalent of the Bearpaw, Judith River, and Lea Park formations in eastern Saskatchewan. The Pierre Shale is comprised of noncalcareous silts and clays, lithologically indistinguishable from those of the Bearpaw and Lea Park formations. Thus, Pierre Shale is present, where the Judith River Formation, which serves as the boundary between Lea Park and Bearpaw formations is absent. The Pierre Shale occurs throughout the eastern portion of the Wynyard area, beyond the depositional 'pinch-out' of the Judith River and beneath the Tertiary "Wynyard Formation" in the northeast part of the area.

Tertiary Undifferentiated

The Wynyard Formation overlies olive, oxidized silt and clay of the Pierre Formation. The term "Wynyard Formation" was used informally by Christiansen (1970) to name a sequence of sediments of Tertiary age, lying between the Pierre Formation and glacial deposits. It is often difficult to distinguish "Wynyard Formation" from Empress Group deposits. The "Wynyard Formation" sediments in ascending order are reported to include: a chert and quartzite gravel, a unit of olive coloured "salt and pepper" friable sand, a unit of light brownish-grey clay and grey to white calcareous silt and clay at the formation base (Henry et. al., 1990). These deposits occur as erosional remnants of Tertiary bedrock and are located in the northeast portion of the Study area (Quill Lakes area).

Drift

Empress Group

Where it is differentiated, the Empress Group (Whitaker and Christiansen, 1972) lies between the bedrock surface and the lower most till. The Empress Group is comprised of stratified gravel, sand, silt, and clay sediments. The basal sand of this group is composed predominantly of quartz and dark minerals; and the basal gravel is composed predominately of well rounded chert and quartzite pebbles. These units are commonly noncalcareous. Upper sand and gravel units of the Empress Group indicate, at least in part a glacial derivation, as indicated by the presence of clasts derived from igneous, metamorphic and carbonate rocks. The upper units are usually calcareous. The Empress Group, therefore, includes both preglacial and glacial deposits. Empress Group sediments in excess of 100m are recorded within the Hatfield Valley (see sec I-I').

Sutherland Group

The Sutherland Group (Christiansen, 1968, 1992) lies above bedrock or the Empress Group and beneath the Saskatoon Group (Table 1). In the Wynyard Area, this unit ranges from 0 to about 150 metres in recorded thickness (Touchwood Hills areas, Section L-L') and is comprised of till and stratified drift. The tills of the Sutherland Group are commonly clayier and harder, have a lower electrical resistivity, and are more difficult to penetrate by drilling than tills of the Saskatoon Group. These two groups can often be differentiated on the basis of carbonate content, the presence of shale fragments in the till, and a weathering zone separating the two groups.

Saskatoon Group

The Saskatoon Group (Christiansen, 1968, 1992) comprises all sediments lying between the Sutherland Group and the present surface. Where it is differentiated in the Wynyard Area this unit attains a maximum thickness of about 100 metres (see Sections: C-C', L-L' and K-K').

The Saskatoon Group is composed of multiple till units and stratified drift (Table 1). The tills of the Saskatoon Group are commonly more sandy, more electrically resistive, and have a higher carbonate content than the tills of the Sutherland Group. The Saskatoon Group is comprised of the

Floral Formation, which consists of multiple tills and stratified units, the Battleford Formation and surficial stratified deposits (Christiansen, 1968, 1992).

Surficial stratified deposits occurs as eolian, glaciolacustrine and glaciofluvial sediments and as alluvial sediments that were deposited by post glacial and/or modern, streams and rivers. In the Wynyard area, large laterally continuous regions of surficial sand deposition are restricted to the areas where spillways discharged into Glacial Last Mountain Lake. Indications of sporadic surficial stratified deposits are encountered in testholes located throughout the Wynyard study areas. The lateral extent of these sediments is highly variable.

HYDROSTRATIGRAPHY

General

In this report a hydrostratigraphic unit consists of a lithologic unit that has considerable lateral extent and comprises a geological framework for a reasonably distinct hydrologic system. This investigation outlines the stratigraphic relationship between these various units in order to assist in the search for groundwater in the Wynyard area .

Groundwater originates from precipitation that infiltrates to the water table, moves downward and laterally under the influence of gravity, and eventually discharges back to the ground surface at some point of lower elevation (Menely,1977). An aquifer is a layer in which a well can be constructed yielding sufficient water for production. Aquifers are separated by aquitards, which are layers sufficiently permeable to transmit water but not sufficiently permeable to allow completion of a production well.

Groundwater moves through the intergranular openings and fractures in the sediments. The water moves under influence of gravity from regions of higher hydraulic head to regions of lower hydraulic head. The hydraulic head generally is expressed as the elevation above sea level of the water level in a well. If the layers are horizontal and of large areal extent, as in this area, the water tends to move vertically in aquitards while in aquifers it moves horizontally. The distribution of the hydraulic head determines the direction of flow. In turn, the hydraulic head distribution is controlled by factors such as topography, stratigraphic setting, and the type of material forming the aquitards and aquifers (Meneley, 1977).

In the Wynyard Area, the Empress Group Aquifers form the most extensive aquifer unit. Less extensive, but significant, aquifers include: Saskatoon Group intertill/interglacial sands and gravels, and surficial sands. Aquifers in the Sutherland Group and Bearpaw Formation sand members constitute minor aquifers in this area. Till units and bedrock clays form the aquitards in the area.

Bedrock Aquifers

General

Bedrock aquifers are those water yielding units which occur stratigraphically below the Empress Group. The base of groundwater exploration defines the depth beyond which it is generally

considered to be uneconomic to explore for groundwater because of the cost of drilling to the required depth and /or because the water at that depth is considered to be too highly mineralized for the intended use (Christiansen, 1970). In the Wynyard area the base of groundwater exploration is defined the base of the Judith River Formation (where it is present) or the top of the Pierre Shale where the Judith River Formation is not present.

Judith River Aquifer

The Judith River Aquifer, occurs in the western portion of the Wynyard Area (Map 3). The recorded depth to the top of this aquifer is variable ranging from 200 metres in the southwest to 50 metres in the northwest (see section G-G'). Where salt collapse is suspected the depth to the top of the Judith River is reported as 370 m below surface. In general the formation thins in an easterly direction (McLean, 1971). The top of the Judith River Aquifer lies between about 100 and 200 m below the ground surface.

Several cross sections indicate that the Judith River Formation Aquifer is hydraulically connected to Empress Group sediments where preglacial erosion has cut through the Bearpaw Formation.

Of the 877 water well records used in the study (i.e. excluding oil wells), 39 indicated the presence of the Judith River Aquifer, and only 13 of these reported a depth to water value. Depth to water ranged from 63 to 12 metres below surface. The Judith River aquifer is a major regional aquifer in the southwest and west central portions of the Wynyard area, however it is usually highly mineralized and utilized only when stratigraphically higher aquifers are not present.

Bearpaw Sand Aquifer

Wells have been completed in a Bearpaw sand aquifer, the Ardkenneth Member, located in the extreme southwest portion of the Wynyard study area (see Map 3, and cross sections E-E', and G-G'). This sandy member of the Bearpaw Formation forms the bedrock surface in this area. It is composed of noncalcareous, fine, light coloured sand and silty sand. Reported water levels range from 61-30 m below surface.

Tertiary Sands and Gravels

Significant sand and gravel deposits of Tertiary age are located, as indicated by records from 58 testholes, in the northeast portion of the Wynyard Area. This material has been informally named the “Wynyard Formation” (Christiansen, 1970). A number of wells (36) indicate water levels in this aquifer range from flowing conditions to 30 metres below surface. Thickness of the unit varies from 0 to approximately 75 metres. Most testholes indicate the formation is deposited over Pierre Shale. This Tertiary aged aquifer is hydraulically connected to the Empress Group sediments, and the two are often indistinguishable without detailed lithological descriptions of the sediments (Maathuis and Schreiner, 1982).

Drift Aquifers

Empress Group

Silts, sands, and gravels that occupy the stratigraphic position of the Empress Group are indicated on Map 4. The Empress Group aquifers are located throughout the central portion of the Wynyard area. The “Hatfield Valley” and its tributaries comprise a significant component of the Empress Group Aquifers in the Wynyard area and, are evident on the bedrock surface topography map (see Map 2). The “Hatfield Valley” aquifer is part of a major preglacial fluvial system which traverses the Saskatchewan from northwest to southeast. The valley is flanked by, and hydraulically connected to, Empress Group sediments which occupy an “upland position” on the flanks of the “Hatfield Valley”. A more detailed discussion of the interconnection of Empress Group aquifers and groundwater flow within them can be found in Maathuis and Schreiner, 1982.

Empress group sediments are indicated in 225 of the water well and testholes records used in this investigation. Depth to and thickness of these aquifers are highly variable. Depth to the top of Empress Group sediments ranged from 20 to 200 metres below ground surface while thickness of Empress Group sediments range from 1 to 137 metres. Static water level varies greatly from reported flowing conditions at 17 locations, to 152 m below ground surface. Several single point locations of Empress Group sediments are also indicated on the map.

Sutherland Group

Sutherland Group aquifers are stratigraphically located within tills of the Sutherland Group and above Empress Group sediments (Map 5). These aquifers are fewer in number and areal extent than are Saskatoon Group aquifers. This is somewhat due to a lack of information, as wells completed into shallow aquifers often did not have testholes drilled to investigate deeper formations. Of the 877 waterwell/testhole records used in this investigation 125 intersected Sutherland Group aquifers. Of these water levels were reported for 54 wells ranging from flowing to 68 m below surface. Most of these Sutherland Group aquifers are located in the northwest to southeast trend which coincides with the location of the stratigraphically lower Hatfield Valley, Empress Group aquifer. Data from a number of isolated wells completed in the Sutherland Group are also indicated on the map. The continuity and interconnection of these aquifers is limited by incomplete stratigraphic information.

Interglacial Aquifers

Interglacial aquifers occur between the lowest till of the Saskatoon Group and the uppermost till of the Sutherland Group. These aquifers are commonly at depths less than 50 m below ground surface. Interglacial aquifers are extensive in the Wynyard Area (Map 6). Of the waterwell/testhole records used in this investigation, 299 intersected interglacial aquifers. Of these water levels were reported for 194 wells ranging from flowing to 111 m below surface. Aquifers located in this stratigraphic position are a very important component of groundwater supply in the Wynyard area. It should be noted that, as with all drift aquifers, the lateral continuity of aquifers in this position is very tenuous, and while some degree of lateral continuity is assumed within each aquifer, additional testhole drilling may prove otherwise.

Saskatoon Group

Saskatoon Group aquifers include the stratified deposits which occur between tills of the Saskatoon Group itself (i.e. Battleford till and Floral till). Of the 877 waterwell/testhole records used in this investigation, only 83 intersected Saskatoon Group aquifers. Water levels, ranging from flowing to 30 m below surface were reported for 45 of these wells. These aquifers are commonly intersected at depths less than 50 m below ground surface.

Saskatoon Group aquifers are located throughout the Wynyard Area (Map 7). Laterally the lithologic and hydraulic continuity of these aquifers is often interrupted.

Surficial Stratified Deposits

Many shallow seepage wells, generally less 15 m deep, have been constructed throughout the area primarily in surficial stratified deposits. Many large diameter, bored wells (not included in this compilation) have been completed in surficial stratified deposits. The extent, as indicated from the testhole and water well records used in this report, of the Surficial Sand aquifer is indicated on Map 8. The largest of these is located north of Last Mountain Lake where fluvial deposits related to the most recent deglaciation are abundant. Water in surficial aquifers originates as precipitation which has infiltrated down from the ground surface to the watertable. Recharge occurs seasonally mainly during the spring snow melt period and during intensive or long duration rainstorms.

Flowing Wells

Flowing wells (i.e. where the static water level is above the ground surface) generally indicate an upward groundwater flow. In the Wynyard Area, flowing wells have been completed into Saskatoon Group, interglacial, Sutherland Group, Empress Group, and bedrock aquifers. Table 2 is a list of 33 reported flowing wells in the Wynyard Area, as reported from the SWC completion records used in this report. In the Wynyard area, the Allan Hills in the west and the Touchwood Hills in the east are the major areas of groundwater recharge and the intervening Last Mountain Lake and Quill Lake lowlands are the major area of groundwater discharge. Most of the flowing wells, regardless of their stratigraphic position, are restricted to this broad discharge area. (Christiansen and Greer, 1963).

APPENDIX I

Index of Cross Section Logs

The following types of logs and records have been used for the compilation of this work.

1. The SRC file contains logs that include E-logs, driller's logs, geologist's descriptions of the cutting samples, and often analytical results.
2. The Oil - Potash logs consist of geophysical logs only. These logs are listed as OIL.
3. The SWC file contains logs consisting of E-logs, driller's logs, and information pertaining to well completion. Collection of this type of data was initiated under the Family Farm Improvement Branch (FFIB) Testhole Assistance Program, which was the forerunner of a similar program now administered by the SWC. These logs are list as SWC.
